ABSTRACT

A METHOD TO IDENTIFY ZONES OF INTENSE JOINTING
WITH APPLICATION TO THE PARSONS LINEAMENT, WEST VIRGINIA

Studies of water well yields, of three roadcuts, and of field observations indicate that the Parsons lineament in eastern West Virginia is a broad, cross-strike zone of unusually intense jointing. To test this hypothesis, strike, dip, exposed length, exposed depth, and spacing of 1594 joints were measured in interbedded siltstones, mudstones, and shales in the Upper Devonian Chemung facies. Joint sets were determined to strike N 35-55° W, N 25-45° E, and N 80° E - N 80° W. SYMAPS show more intense jointing within the Parsons lineament with the northeast-trending set contributing most to the increase. Identification of zones of intense jointing could be useful in hydrocarbon exploration, mine design, construction, and water-well siting.

INTRODUCTION

Anomalously intense jointing has often been cited as a reason for some gas production from fractured shales, coal mine roof falls, construction problems, and increased water-well yields. Accordingly, a method for measuring joint intensity and locating areas of intense fracturing would be generally useful. As part of the Eastern Gas Shales Project, funded by the Department of Energy, such a method was developed (Wheeler and Dixon, 1979). This paper reports a field test and application of the method. My purpose is to characterize exposed systems of natural fractures that are considered to be analogues of fractured gas reservoirs still buried further west, in central West Virginia (Wheeler, 1978a; 1978b).

SETTING

The Parsons lineament in the Plateau Province in eastern West Virginia was chosen for this study because previous studies (Wheeler and others, 1978; Wheeler and Holland, 1978a; 1978b) indicated that rocks in the lineament are more intensely jointed than rocks juxtaposed to the lineament. The lineament is a northwest trending band, from 7 to 10 km wide, of disruptions in the regular northeast-trending folds and detachments characteristic of the eastern Plateau Province (Gwinn, 1964; Cardwell and others, 1968). The lineament extends at least 55 km, according to terrain corrected gravity, topographic, and LANDSAT data. This paper deals with systematic joints in interbedded siltstones, mudstones, and shales of the Upper Devonian

Chemung facies. Only the Chemung was studied in order to reduce the effects of differing lithologies. Bed thicknesses range from 0.2 to 200 cm, and typically are 10 to 30 cm. In Tucker County, the Parsons lineament crosses the outcrop belt of Chemung rocks exposed in the cores of the northeast-trending Deer Park and Elkins Valley anticlines (Cardwell and others, 1968; Gwinn, 1964).

METHOD

A total of 1594 joints were measured at 143 stations in the Chemung facies (Figure 1). As many as possible of strike, dip, exposed depth, exposed length, spacing, and bed thickness were measured on each joint. Exposed depth is the total exposed extent of a joint in the direction perpendicular to bedding, and exposed length, parallel to bedding; spacing is the perpendicular distance to the adjacent joint in the same set (Stubbs and Wheeler, 1975; Wheeler and Stubbs, 1979). Bed thickness is a measurement of the thickest bed through which the joint penetrates. Exposure size, regularity or irregularity of spacing, and number of joint sets exposed determined the number of measurements taken per station. Fifty-four percent of the joints were measured in roadcuts; the rest in streamcuts and stream pavements. Statistical analyses and contour maps of joint intensity and spacing were done with local modifications of the Statistical Analysis System and of the SYMAP program.

Jeanette M. Dixon

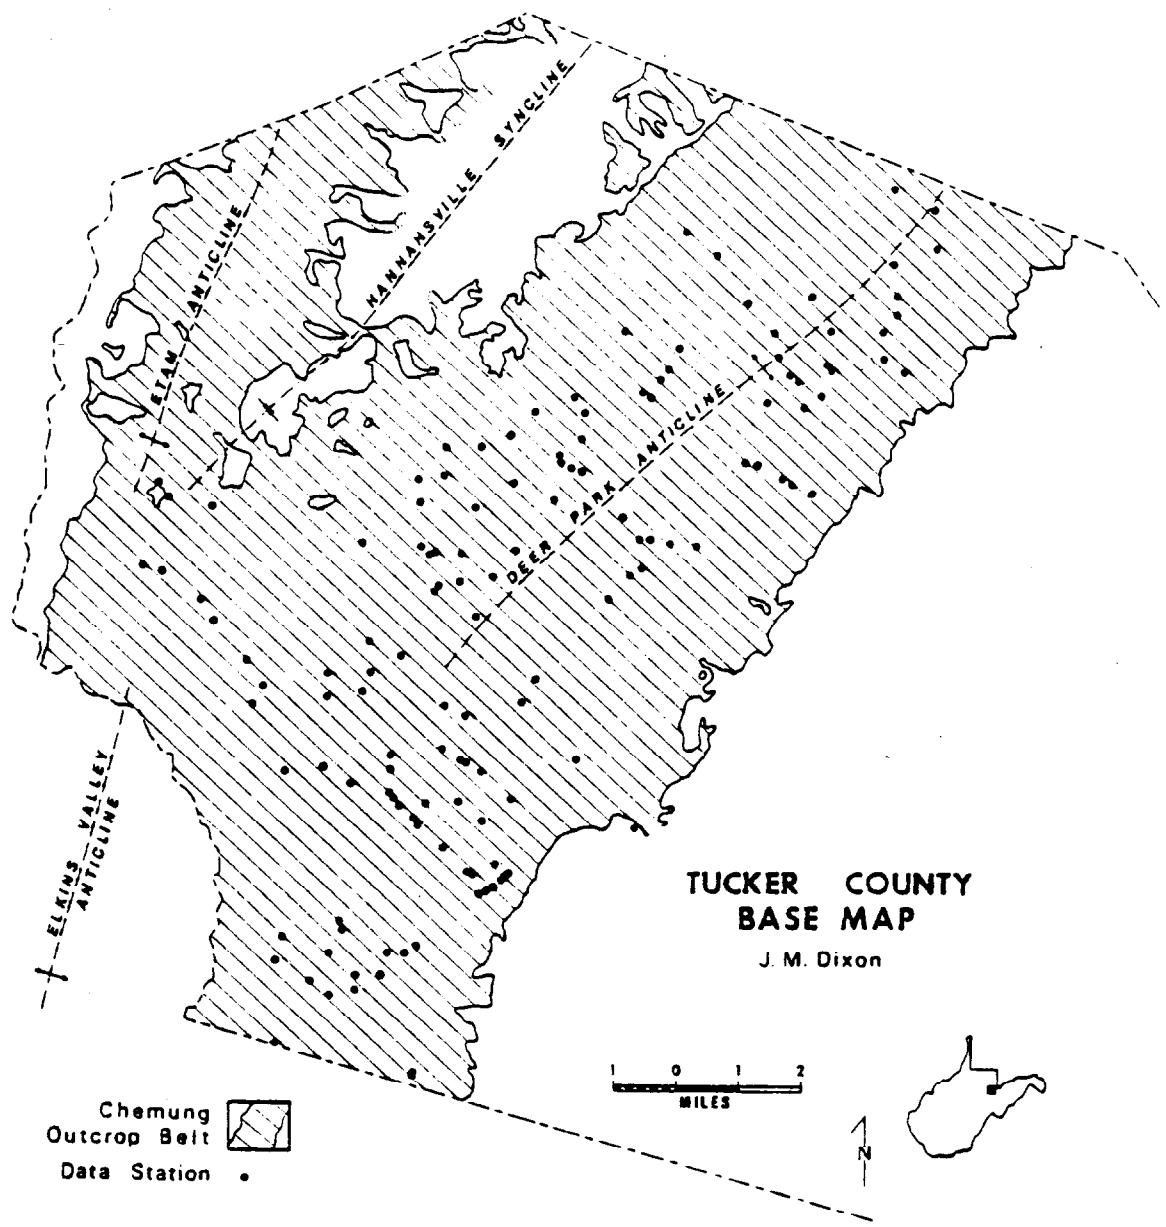

Figure 1. Index map showing the extent of the Chemung Outcrop belt and station locations.

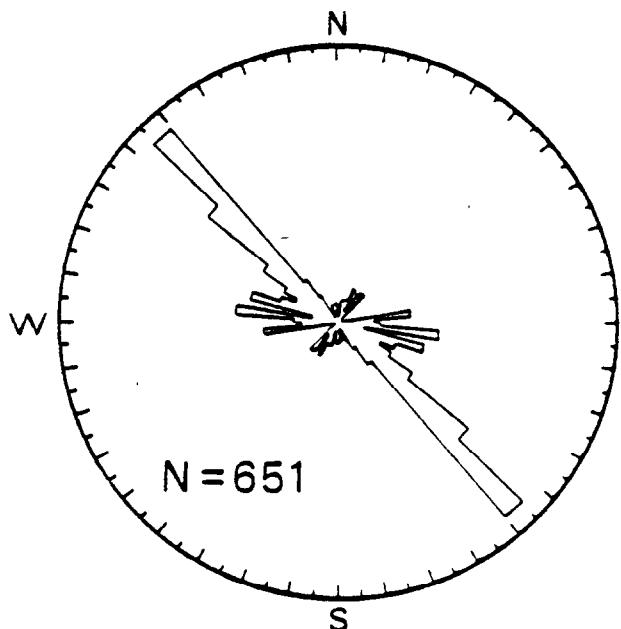

RESULTS

A circular histogram of all measured joints shows three sets: N 35-55° W (transverse to folds), N 25-45° E (longitudinal), and N 80° E - N 80° W (diagonal), with the northwest set dominating (Figure 2). Roadcuts and stream exposures each show all three sets (Figure 3). All three sets appear north, within, and south of the lineament, but in different abundances (Figures 2a, b, c). In addition, a N 05-10° W set appears south of the lineament (Figure 2c).

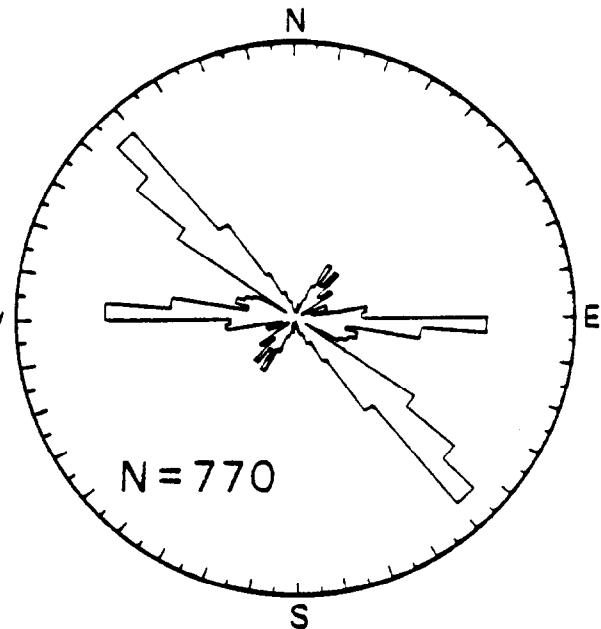

A measurement of joint intensity, joint surface area per unit volume of rock (Wheeler and Dixon, 1979; Wheeler, 1979), was made using inverses of average spacings, summed over all sets in an exposure (Vallon and others, 1976; Wheeler, 1979; Dixon, 1979).

SYMAP shows areas of more intense jointing within the lineament (Figure 4). The map was shown to five people: independently, each chose the boundaries of the lineament where shown in Figure 4. SYMAPS of average spacing for individual sets indicate that the northeast-striking set contributes most to the increased intensity inside the lineament, the northwest-striking set contributes slightly, and the east-striking set contributes little, if at all (Figures 5, 6, and 7). Mean spacings of each set support that (Table 1).

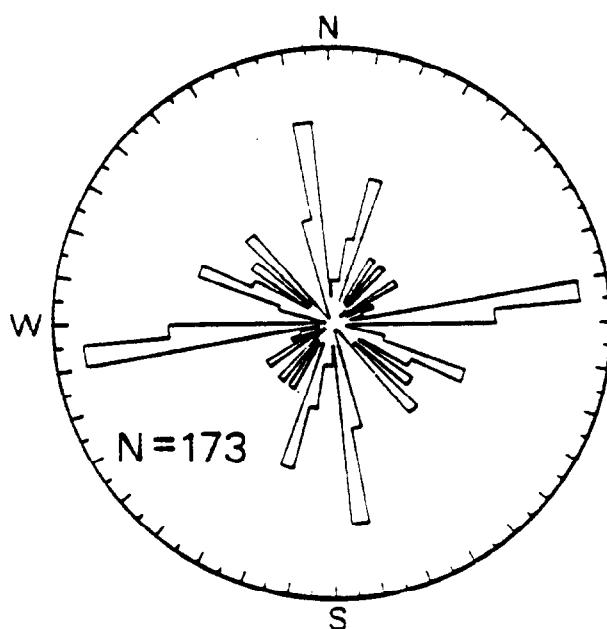

A SYMAP of average bed thickness shows a northeast-trending band of thin beds, reflecting the thinner beds of the lower Chemung facies exposed along the crest of the Deer Park and Elkins Valley anticlines (Figure 8). The trends found in the spacing and intensity

Table 1. Mean spacing in cm (\bar{s}), number of observations (n), and standard deviations in cm (σ_s) of each joint set north, within, and south of Parsons lineament.

maps are northwest to north, from which I conclude that a factor other than bed thickness controls joint intensity. (Statistical tests show only a minor correlation between bed thickness and joint spacing.) That factor apparently is the Parsons lineament.

Large, northeast-trending anticlines plunge into the Parsons lineament (Figure 1; Cardwell and others, 1968), which may have increased the intensity of the transverse joint set on the anticlinal noses. Smaller, northeast-trending anticlines with wavelengths on the order of half a kilometer are more numerous in the lineament (Trumbo, 1976), and may increase the intensity of the longitudinal set.

CONCLUSIONS

1. The Upper Devonian Chemung facies shows three well-developed, systematic joint sets: N 35-55° W, N 25-45° E, and N 80° E - N 80° W, with the northwest set dominating.
2. Rocks within the Parsons lineament are more intensely jointed than rocks juxtaposed.
3. SYMAPS and statistics show the northeast-trending set contributes most to joint intensity, the northwest-trending set slightly contributes, and the east-trending set contributes little or not at all to increased joint intensity within the Parsons lineament.
4. Joint spacing was found to be the most useful measurement in determining joint intensity.
